TITLE: Broad ligament hernia: A rare cause of small bowel obstruction

ABSTRACT

Introduction
The broad ligament is a peritoneal fold attaching the fallopian tubes, ovaries and uterus to the wall and floor of the pelvis: herniation of abdominal viscera through a defect in this structure is rare and accounts for 4% of all internal hernias.

Case Report
We present the case of a 73-year-old woman with no prior surgical history presented to the emergency department with a 4-day history of abdominal distension, bilious vomiting and not opening her bowels. CT abdomen and pelvis showed a dilated small bowel with a transition point in the distal ileum with no definite cause of obstruction identified. As conservative management did not relieve her symptoms she was consented for a diagnostic laparoscopy which revealed internal herniation of distal ileum through a defect in the broad ligament of the uterus.

Conclusion
Small bowel obstruction due to internal herniation through a defect in the broad ligament is very rare. This diagnosis should be considered when radiological imaging is inconclusive. Early recognition is extremely important to reduce the risk of intestinal strangulation which has a high mortality rate.

Keywords: Internal Hernia, Broad ligament, Small bowel obstruction, Laparoscopy
INTRODUCTION

Internal hernias are rare and occur when there is protrusion of a hollow viscus (more commonly the small intestine) intra-abdominally through a congenital or acquired opening within the peritoneum or mesentery. Up to approximately 6% of cases of intestinal obstruction are due to internal hernias [1,2]. The broad ligament is a peritoneal fold attaching the fallopian tubes, ovaries and uterus to the wall and floor of the pelvis: herniation of abdominal viscera through a defect in this structure is rare and accounts for 4% of all internal hernias [2,3,4,5]. Herein we report the case of small bowel obstruction due to a broad ligament hernia, managed successfully using laparoscopic techniques.

CASE REPORT

A 73-year-old woman with no prior surgical history presented to the emergency department with a 4-day history of abdominal distension, bilious vomiting and not opening her bowels. On physical examination her abdomen was markedly distended, but soft, non-tender with tinkling bowel sounds. Rectal examination revealed no abnormalities. Laboratory findings showed raised inflammatory markers: CRP 123 mg/l and plain film radiography revealed dilated small bowel loops (Figure 1). A CT abdomen and pelvis was subsequently performed which showed dilated small bowel with a transition point in the distal ileum with no definite cause of obstruction identified. Initially, she was managed conservatively with naso-gastric tube decompression, intravenous antibiotics and fluids with little improvement of her symptoms. Therefore a diagnostic laparoscopy was undertaken. Intra-operative findings revealed internal herniation of distal ileum through a 3x3cm defect in the broad ligament of the uterus (Figure 2, 3). The small bowel had no evidence of ischaemia therefore was simply reduced and the defect of the broad ligament was closed with 2-0 vicryl stitches (Figure 4). Post-operatively her symptoms completely resolved leading to her discharge 3 days later.
DISCUSSION

There are various types of internal hernias described in the literature; most commonly reported in 53% of cases are paraduodenal. Others examples include pericaecal (13%), transmesenteric (8%), and epiploic foramen hernias (8%) [1,2]. However, intestinal herniation through the broad ligament is the least common and only accounts for 4% of all internal hernias [4,5]. Causes of these are either congenital or acquired in nature: usually due to obstetric trauma, abdominopelvic surgery, or pelvic inflammatory disease [5]. Therefore in a woman with a virgin abdomen and no significant medical history, a congenital cause must be considered.

There are two classification systems described in the literature which can be used to categorise defects within the broad ligament. The first was described by Hunt in 1934 and is based on the degree of peritoneal extension. The most common is the fenestra type, which involves both peritoneal layers, as small bowel can pass directly through this it can potentially lead to bowel strangulation. The pouch type is where only one of the two peritoneal layers is affected and may allow viscera to become trapped within parametrial tissue [6]. The second was devised in 1986 by Cilley which classified broad ligament hernias into 3 main categories based on the location of the defect within the broad ligament. Type 1 defects are the most common and occur in the mesometrium, which contains the greater section of the broad ligament. Type 2: interrupt the mesosalpinx and the mesovarium. Type 3: arise within the centre of the round ligament [7]. The patient in the case described above had a Type 1, fenestra broad ligament defect (Figure 3).

Unfortunately, clinically and radiologically internal hernias are very difficult to diagnose and a diagnostic delay is reported to have a mortality rate of approximately 50% due to the high risk of strangulation [2,5]. Laparoscopic techniques are therefore extremely important as it allows early recognition and prompt surgical management, which includes reduction of the herniated bowel, potential resection and repair of the defect [8-10].

CONCLUSION

Small bowel obstruction due to internal herniation through a defect in the broad ligament is very rare. This diagnosis should be considered when radiological imaging...
is inconclusive. Early recognition is extremely important to reduce the risk of intestinal strangulation which has a high mortality rate.
